## Abstract

Population ageing represents a “triumph” and a “challenge” for society.

The increase in life expectancy corresponds to an increase of risk factors and age-associated non communicable diseases, with consequent rise in health care costs and the burden of healthcare sustainability.

Aim of this analysis is to describe the prevalence of non communicable diseases, comorbidity and disability in non-institutionalized elderly population, aged 75-79 years, examined within the Osservatorio Epidemiologico Cardiovascolare/Health Examination Survey.

Cardiovascular disease is the most frequent occurring in 27% of the examined population, followed by diabetes (24%) and chronic kidney disease (21%); 60% of examined elderly population suffers of one or more chronic diseases, while 40% is in a good health.

Ninety-three per cent of the examined population is free of disability; cognitive function disorders, assessed by the Folstein's Mini Mental State Examination, are recorded in 21% men and 29% women.

In the context of prevention, there is still much that needs to be done. It is important to initiate or maintain preventive actions concerning also this age-group at both community and individual level, to promote the cultural notion that a good quality of life in advanced age is built day by day starting from one's youth through a healthy diet, regular physical activity and non-smoking habit.

## Introduction

Italy continues to be one of the countries with the highest proportion of people aged ≥65 years in the world – today this age-group constitutes 20% of the population. The latest ISTAT (National Bureau of Statistics) projections indicate that in 2051 one-third of all Italians will be 65 years or older. According to data from the WHO Global Burden of Disease Study 2010 Country Profiles, life expectancy in Italy is 81.5 years and in the last 10 years, among countries with similar income level, Italy has passed from 4<sup>th</sup> to 2<sup>nd</sup> position after Japan, and is ranked 3<sup>rd</sup> in terms of years lived in good health (70.2 years) [1]. Population ageing represents both a “triumph” and a “challenge” for society. The general increase in life expectancy corresponds to an increase in age-linked chronic degenerative diseases, with a consequent rise in healthcare costs and the burden of healthcare sustainability.

In the face of this scenario, the WHO has recently outlined a strategy of health promotion and support of the elderly person, designated with the name “Active Ageing”, whose aim is to promote a new concept of ageing and enhance the quality of life of elderly people in society [2]. To support this strategy, it recommends the implementation of health population and health care surveillance. Hence, now more than ever before it is necessary that the planning and implementation of interventions be based on systematic, detailed quality information on the needs of the elderly population, and on the evolution of the health and social issues linked to ageing. This information is essential to assess the efficacy of the actions already undertaken, rationalize the available resources, and redress the widening gap of health and social inequalities within this age-group of the population. This information is available thanks to data collected through the Osservatorio Epidemiologico Cardiovascolare/Health Examination Survey carried out in the framework of the ANMCO-HCF-ISS joint agreement [3].

## Materials and Methods

The Osservatorio Epidemiologico Cardiovascolare/Health Examination Survey was an cross-section epidemiological survey conducted between 2008 and 2012 on representative samples of the general population aged 35-79 years (the samples were extracted from the lists of residents of 23 municipalities which adhered to the survey, distributed throughout 20 regions of Italy), the samples consisting of 220 persons every 1.5 million inhabitants. All procedures and methodologies adopted in the screening process were in accordance with the recommendations and international quality controls, and have been amply described elsewhere [3,4]. In the age-group considered here (75-79 years), the subjects who participated represented only 50% of those enrolled; hence these data, although indicative, should be interpreted with caution and, given the age, they could represent that part of the non-institutionalized population with the best health status.

The diagnostic criteria adopted relative to the diseases considered were, briefly, as follows: respiratory diseases included bronchial asthma and diagnosed chronic obstructive pulmonary disease (COPD); chronic kidney disease (CKD) was defined as glomerular filtration rate <60 mL/min/1.73m<sup>2</sup> or urine albumin/creatinine ratio ≥30 mg/g; diabetics were defined as having fasting glycemia ≥126 mg/dl or if under specific treatment; cardiovascular diseases (CVD) included the following conditions: myocardial infarction, stroke, angina pectoris, atrial fibrillation, left ventricular hypertrophy, transient ischemic attack, intermittent claudication as documented in the patient's medical record or defined by means of a specific standardized questionnaire and the ECG Minnesota code classification [5]; presence of cancer was based on patient self-report and review of the patient's medical record; chronic liver disease was also defined by patient self-report and review of the medical record.

Disability was analyzed in those who completed the Instrumental Activities of Daily Living (IADL) questionnaire, in particular the ability to: use the phone, take medications, manage one's finances, and do shopping; for the assessment of Basic Activities of Daily Living (BADL), the following items were added: eating without need for assistance, getting dressed and undressed without need for assistance, having a shower or bath without need for assistance [6].

Finally, the Mini Mental State Examination (MMSE) was considered for the assessment of cognitive deficit, adjusted for age and educational level; subjects who scored lower than 24/30 were considered as having a cognitive decline [7]. This parameter was analyzed on a smaller number of subjects in that the questionnaire was administered in only 14 out of 20 regions.

**Table 1.** Osservatorio Epidemiologico Cardiovascolare/Health Examination survey: prevalence of the major chronic diseases in the non-institutionalized population aged 75-79 years.

Chronic diseases	%	95% CI
Chronic respiratory diseases	15.4	12.8 18.0
Chronic kidney disease	20.7	17.6 23.7
Diabetes	23.6	20.6 26.6
Cardiovascular diseases	27.0	23.9 30.1
Cancer	9.8	7.6 11.9
Chronic liver diseases	0.7	0.1 1.2

**Table 2.** Osservatorio Epidemiologico Cardiovascolare/Health Examination survey: prevalence of the main physical disabilities from the IADL and BADL in the non-institutionalized population aged 75-79 years.

IADL	Disability		CI	BADL	Disability		CI
	%	95%			%	95%	
Use of telephone	2.5	1.1-4.0	Eating without aid		1.1	0.2-2.2	
Taking medications	2.5	1.1-4.0	Getting dressed/undressed on one's own		2.5	1.1-4.0	
Managing finances	3.8	2.0-5.6	Bathing or showering alone		2.2	1.1-3.6	
Doing shopping	5.8	3.6-8.1					
N. disabilities IADL		N. disabilities BADL					
0	92.8	90.4-95.1			0	96.6	94.9-98.2
1	3.6	2.0-5.4			1	1.6	2.0-5.4
2	1.3	0.4-2.5			2	1.1	0.4-2.5
3	0.7	0.0-1.6			3	0.7	0.0-1.6
4	1.6	0.5-2.7					

## Results

The data reported below refer to 799 non-institutionalized individuals (429 males and 370 females), aged between 75 and 79 years, distributed throughout 20 Italian regions. Table 1 reports the prevalence of the principal chronic diseases based on the diagnostic criteria adopted by the study and reported above in the Methods. As can be clearly seen, CVD, CKD and diabetes showed the highest prevalence. No chronic disease was present in 37.4% [95% confidence interval (CI): 33.6-41.1] of participants, while 19% (CI 15.9-22.0) had 2 diseases, and 6.8% (CI 4.8-8.7) had 3 or more diseases. Among those with at least two comorbidities, CVD and diabetes were the two most frequently combined (26.8%), followed by CVD and respiratory diseases (13.4%), CVD and cancer (12.2%), CVD and CKD (11.6%), and CKD and diabetes (10.4%). Arterial hypertension was the most prevalent high-risk condition found in this age-group, being present in 78.3% (74-82) of men and 81.3% (CI 77-83) of women. Of the men with hypertension, 25% were not aware they had this condition, while 18.7% of the women were not aware they had hypertension. Only 30% of the men with hypertension and 22.3% of the women with hypertension were receiving adequate healthcare, while 42% of men with hypertension and 54% of women with hypertension were not below the satisfactory level of 140/90 mmHg.

Table 2 reports data on disability for the principal items of IADL: 92.8% of participants had no physical disability. Doing the shopping was the item reported as posing most difficulty. Table 2 reports also disability in the BADL: 96.6% of participants reported not having any disability, while getting dressed and undressed alone (without the need for help) was reported as the most compromised activity.

The mean score on the MMSE, adjusted for age and education, was 25.7 for men and 25.0 for women; an age- and education-adjusted score <24 was found in 21.4% of men and 29% of women (Table 3).

**Table 3.** Osservatorio Epidemiologico Cardiovascolare/Health Examination survey: mean score on the Mini Mental State Examination (mean ± standard deviation) and prevalence of cognitive decline in non-institutionalized males and females aged 75-79 years.

	Males	Females
MMSE score	25.7±3.6	25.0±4.0
MMSE<24/30	21.4% (CI 16.5-26.6)	29.0 (CI 23.1-35.2)

## Discussion

When speaking about life expectancy, it is necessary to estimate the life expectancy also in terms of years lived in good health. Notwithstanding an overall improvement in health status, and the progress in awareness about risk factors and the possibility of preventing disease, people today live in good health until 70 years of age, but the following 10 years are lived in non optimal conditions due to the presence of a cardiovascular disease, often associated with other chronic-degenerative diseases (diabetes, respiratory disease, cancer, CKD, or liver disease); CVD can be prevented also in advanced age thanks to the availability of highly effective therapies and the greater awareness of the beneficial effects of a healthy life style at whatever age [8]. For this reason, it is necessary to start preventive actions at both individual and population level to improve the conditions of life in advanced age.

The data from the Osservatorio Epidemiologico Cardiovascolare/Health Examination Survey on the 75-79 year age-group across all regions of Italy show that almost 60% of elderly persons in this age-group suffer from a chronic-degenerative disease, but the remaining 40% enjoy good health status; 80% are affected by a condition such as arterial hypertension, which constitutes one of the principal factors for the development of CVD and age-related diseases, but the data we gathered show that only 30% of the men and 22% of the women are on adequate treatment. Disability in this age-group is still limited to a small number of people, inferior to 6-7% of the sample surveyed. More preoccupying are the cognitive decline, in that more than 20% of men and 29% of women are affected by a cognitive decline. We should not forget, however, that the rate of participation in this age-group was 50%, and normally the people who present for an active screening are the ones who know they have a better health status. In the context of prevention, there is still much that needs to be done. It is important to initiate or maintain pre-

ventive actions concerning also this age-group at both community and individual level. It is fundamental to promote the cultural notion that a good quality of life in advanced age is built day by day starting from one's youth through a healthy diet (varied, well-balanced and of modest portions), regular daily physical activity, and nonsmoking.
